There are many important ingredients in a successful livestock production system. One of the most important tasks is to keep detailed records on livestock stocking rate, livestock performance, and forage production. Forage production and stocking rate records are critical in making timely management decisions. No other single management practice affects profitability of livestock more than stocking rate. This publication discusses how to determine the proper stocking rate for your land.

Some Working Definitions

In order to discuss stocking rate and its effect on animal performance, it is necessary to establish some definitions. Stocking rate is defined as the number of animals on a given amount of land over a certain period of time. Stocking rate is generally expressed as animal units per unit of land area. Carrying capacity is the stocking rate that is sustainable over time per unit of land area. A critical factor to evaluate is how well the stocking rate agrees with the carrying capacity of the land. A term that is used to help understand and estimate forage requirements is the animal unit (AU) concept (Table 1).

Calculations

A livestock producer has 50 head of 1,000-lb cows on 200 acres for 12 months. The stocking rate of this operation would be calculated as follows:

Example 1: Calculation of stocking rate:

$$\text{Total Land Area ÷ \left[\text{(# AUs) x (Grazing Season)}\right]} = \text{Stocking Rate}$$

$$200 \text{ acres ÷ \left[\left(50\text{ AUs}\right) x (12 \text{ months})\right]} = 0.33 \text{ acres per AU month (AUM) or 4 acres per AU year (AUY)}$$

Calculating stocking rate is relatively simple once the concept and terminology are understood. The ability to calculate stocking rate and make timely management decisions is vital to maximizing net returns from the livestock operation.
Differences in Stocking of Introduced and Rangeland Forages

Although the concepts of stocking rate determination are similar for introduced and rangeland forages, there is one major difference in estimating stocking rate: allowable use (percent utilization of available forage) is lower for rangeland forage. This cannot be emphasized enough; introduced forages can be utilized to a higher degree than rangeland forages if adequate moisture and fertility are available. Working through some examples for both types of systems should help clear up any misunderstanding. Utilization does not equal consumption by the animal for any kind of forage. Utilization includes decomposition, waste, and consumption by insects and other herbivores.

Stocking Rates on Introduced Forages

Introduced forages are generally non-native species that have been selected for rapid growth and grazing tolerance. Introduced forage grasses common to Oklahoma include bermudagrass, tall fescue, Old World bluestem, weeping lovegrass, various cereal grains, and ryegrass. Oklahoma producers also use several introduced legumes, including alfalfa, hairy vetch, and numerous clover species (red, white, arrowleaf, rose, berseem). Most introduced forages will tolerate a heavier degree of grazing pressure than rangeland forages because of their rapid regrowth capabilities. Although many introduced forages are tolerant of close grazing, not all the forage produced can be removed. Some residue must be left for the plant to carry out basic metabolic functions.

Table 3 contains suggested residue levels for some forages commonly used in Oklahoma. This information will help prevent overgrazing of pastures.

Using the information in Tables 2 and 3, producers can quickly estimate the animal forage demand and the stocking rate for their livestock production system. For fine tuning of stocking rates on specific ranches; however, forage production information from long-term record keeping will be necessary because long-term data takes into account fluctuations in precipitation. Moisture is generally the most limiting factor relative to forage production.

Example 3: Calculation of available forage for grazing:

\[(\text{Average DM in lbs. per acre}) \times (\# \text{ Acres}) \times (\% \text{ Utilization Factor})\]

\[= 5,000 \times 100 \times 0.65 = 325,000 \text{ lbs. of Forage DM}\]

Next, estimate the number of animal units that could be stocked on the pasture given the above forage production potential. In other words, calculate the stocking rate in AUs.

Example 4: Calculation of stocking rate (\# head) based on available forage:

\[\left(\frac{\text{Total Forage DM}}{\left(\# \text{ Grazing Days} \times (\text{Daily Forage Demand for 1 AU or AUE of the animal in question})\right)}\right) = \# \text{ of Head}\]

\[= 325,000 \div \left(\frac{120 \text{ days} \times (15 \text{ lbs. DM per day})}{325,000 \div 1800 = 181 \text{ Head}}\right)\]

In this example, a bermudagrass pasture was assumed to be capable of producing 5,000 lbs. of forage DM per acre and it was estimated that a stocking rate of 181 head of 500-lb. stocker calves could be used for a typical 120-day growing season. To express this production scenario as a stocking rate, you would return to the equation used in Example 2.
Example 5: Calculation of AUs from AUEs:

# Head x AUE = Total AUs
181 Head x 0.6 = 109 AUs

Now simply use the equation developed in Example 1 to calculate the stocking rate.

(Total Land Area) ÷ (# AUs) = Stocking Rate
100 ÷ 109 = 0.92 acres per AU

Stocking Rates on Rangeland

Rangeland is the most abundant type of land in Oklahoma and contributes heavily to the beef cattle and recreational leasing industry. Rangeland is the primary source of wildlife habitat throughout the state. Lands that are dominated by native grasses, forbs, shrubs, or scattered trees are considered rangelands. In order for rangeland to be sustainable for beef cattle production, the number of animals and their forage demand must be balanced with forage production. Forage production varies from year to year because of changes in precipitation (Fig. 1-2). Stocking rate should be based on average long-term end-of-season standing crop values (Fig. 2) for an operation to remain productive and sustainable. The procedure for calculating stocking rates can be used on either forests or rangelands.

Ecological Sites and Soils

An ecological site, previously known as a rangeland site, is an area of land with a combination of soil, climatic, topographic, and natural vegetation features that set it apart significantly from adjacent areas. Ecological sites are expressed in terms of soil depth, topography, slope, plant production, and species composition. Vegetation on a particular site will vary in composition and production from one region of the state to another and from year-to-year because of changes in precipitation.

Forage Production and Standing Crop

Stocking rates are based on the amount of forage that is standing at the end of the growing season in an ungrazed condition. End-of-season standing crop is not total production because much of the production has been lost to decomposition and insects. Actual forage production is often twice as large as the end-of-season standing crop. Forage production information is useful but is very time consuming to obtain. That is why end-of-season standing crop is used for estimating stocking rate.

Standing crop should be measured by clipping within grazing exclosures in key areas. The exclosure should be moved each year during the winter. The more years of standing crop information that can be assembled, the better the stocking rate decisions will be. Otherwise, producers must rely on guesses or information from Standard Soil Surveys, which tend to underestimate standing crop.
Stocking Rates and Harvest Efficiency

The recommended stocking rates for rangelands are based on moderate utilization (economic long-term optimum) of the annual forage standing crop and assume uniform grazing distribution. It is also assumed that 50% of the annual peak standing crop can be removed from the ecological site without negatively affecting the plant community relative to species abundance or for beef cattle production. This is the origin of the “take half and leave half” rule-of-thumb that is often used. This is also the source of difference in stocking rate management between rangeland and introduced forages.

Of the 50% of rangeland forage (grasses or forbs) that is assumed to be removed, the assumption is also made that one-half (25%) of the total) is actually consumed by livestock and the other one-half (25% of the total) is trampled, laid on, consumed by insects or other animals, or disappears because of decomposition. These assumptions lead to a harvest efficiency of 25%. Another way to look at this is to assume that 25% of the total forage is actually consumed by the grazing animal. Plant requirements regarding remaining residue and waste by grazing animals set these limits. Harvest efficiency, however, can be increased by using rotational stocking (Table 4). This calculation should be adjusted for the presence of bulls, replacement heifers, or other grazing animals.

Assume 100 head of cows that average approximately 1,000 lbs. with calves on a 1,000-acre rangeland pasture. The goal for this cow herd is continuous stocking for 12 months. The stocking rate would be calculated using information contained in Table 1.

Example 6: Calculation of stocking rate:

For a 1,000 lb. cow, AUE = 1.0 (Table 2)
(100 head) x (1.0 AUE) = 100 AUs
(Total Land Area) ÷ [[(Total) x (grazing season)]
1,000 acres ÷ [[(100 AUs) x (12 months)] = 0.83 acres per AUM or 10 acres per AUY

</tbody>
</table>

Next, use forage standing crop to calculate how many stocker cattle this 1,000 acres of rangeland can carry. From clipping data, it was determined over the past 10 years the average peak forage standing crop was 6,360 lbs. per acre from the monitoring program (Fig. 2).

Using these forage standing crop values, one can estimate how many cows could be stocked on this ranch. Using a 25% harvest efficiency for rangeland forages, the stocking rate is estimated as follows:

Example 7: Calculation of available forage for grazing:

(Average Standing Crop) x (% Utilization Factor) x (Total Acres) = Available Forage
(6,360 lbs.) x (25%) x (1,000 acres) = 1,590,000 lbs. Available Forage

Example 8: Calculation of AUs based on available forage:

Available Forage ÷ [(# Days in Grazing Season) x (Daily Forage Demand)] = # AUs
1,590,000 lbs. ÷ [(365 days) x (26 lbs. per day)] = 168 AUs (cows) for 1 year
1,000 acres ÷ 168 AUs = 6 acres per AUY

A slight twist on the calculation would be to assume livestock smaller than the standard AU. Let us assume calves with an AUE of 0.6 (500-lb. calves) that are to be grazed all year.

1,590,000 lbs. ÷ [(365 days) x (26 lbs. per day)] = 168 AUs
168 AUs ÷ 0.6 AUE = 280
Therefore, 280 calves that weigh 500 pounds could be stocked on this same amount of forage.

Example 9: Calculation of AUs from AUEs:

(# Head) x (AUE) = Total AUs
170 head x 1.0 = 170 AUs or for livestock smaller than 1AU
170 head X 0.6 = 102 AUs

Note: Cows should usually be assigned the AUE of about 1.4 because of the presence of bulls and replacements.

Forage Utilization

Forage utilization of key plant species must be known in order to effectively adjust the stocking rate of rangeland forages. Therefore, you must be able to identify the key plant species of each ecological site. Forage utilization can be monitored throughout the year using a utilization class ranking system of 1 through 5 (Table 5). Utilization is measured by rating the standing crop of native grass inside and outside the grazing enclosure. A utilization score of 3 should be the annual goal. In order to get an accurate picture of forage utilization on rangeland, a systematic grid should be established (Fig. 3).

The grid is observed at several different times during the grazing season and a utilization class ranking (Table 5) is

Forage utilization on rangeland, a systematic grid should be established
by rating the standing crop of native grass inside and outside
Forage utilization of key plant species must be known
since the standard AU. Let us assume calves with an
A slight twist on the calculation would be to assume livestock
assigned to each area. A grazing utilization pattern can then
be developed to assess the harvest efficiency. Producers
will often find that the same areas are either under-utilized or
over-utilized each year (Fig. 4). If utilization scores are above
or below 3, then corrective measure should be taken such
as developing new water sources, moving mineral feeders,
developing new fencing patterns, and the application of pre-
scribed fire.

Another method of judging grazing utilization is measuring
the height of key grazing species throughout the pasture
(Table 6). This method requires a measuring device and a
systematic grid similar to the previously described method.
Utilization heights are different for different ecological sites
and different regions of precipitation. In forests or savannas,
use the height for tallgrass prairie.

Once a grazing pattern is evident, you must then decide
whether improvements such as building cross fences, spray-
ing herbicides, developing new water sources, or changing
stocking rates will improve the profitability of the operation.
Using the previous examples, producers with good forage
production records can determine the proper stocking rate
for their land.

**Stocking Rate Effects on Livestock Production Systems**

Overstocking of rangeland, or overstocking introduced
forages coupled with a poor fertility program, typically leads
to a reduction in desirable forage species and an invasion of
weeds and undesirable grasses such as broomedge and
threawn. As the incidence of undesirable species increases
at the expense of the more desirable forage species, animal
performance declines and the carrying capacity of the grazing
management unit is reduced. This situation is characterized
as an overgrazed situation because of a change in forage
species. The results are decreased profitability both from
a livestock production standpoint and the possible need for
expensive herbicide applications.

Conversely, understocking results in patch (or spot)
grazing. Patch grazing occurs where animals repeatedly
graze the same area as soon as regrowth is available. Ani-
mals continue to utilize previously grazed areas because the
immature regrowth is more palatable and of higher nutritive
value. Ungrazed areas in the pasture continue to increase in
maturity, decline in nutritive value, and become increasingly
less palatable. The decline in forage utilization (harvest effi-
ciency) results in wasted forage and decreased profit potential
from the livestock operation. In either case, proper stocking
rate and some form of rotational stocking could improve the
net profitability of the livestock production system.

Stocking rate has a major impact on animal performance
and overall profitability of the livestock production system. Fig-
ure 5 indicates that maximum individual animal performance
occurs at light stocking rates because there is little competition
for the best forage plants in the pasture. As stocking rate is
increased, the level of animal performance is reduced due
to increased competition. The opportunity for diet selection
afforded by low stocking rates ensures that individual animal
performance is maximized. Figure 5 also indicates that as
stocking rate increases, the amount of weight gain produced
per acre is increased up to a threshold and then declines.

A famous football coach once commented that three
possibilities exist when you throw a forward pass, and two
of the three were bad. The same situation exists for stocking
rate; three possibilities exist (correct stocking, over-stock-
ing, under-stocking) and two of them are unacceptable in
a production system. The most important aspect of Figure
5, however, illustrates the stocking rate at which maximum
net return occurs. This generally takes place at a moderate
stocking rate, or a compromise point between forage resource
conservation and animal performance.

Moderate stocking rate will vary according to those forage
species used in the specific production system. Producers
who continually use heavy stocking rates in an attempt to
improve net profitability, however, should realize that they
have already passed the point at which maximum net return
may be realized.
Summary

Stocking rate is the key element to successful livestock production. The use of improper stocking rates can reduce both the vigor of desirable forage species and animal performance. This results in decreased profitability and sustainability of the production system.

Introduced forages generally have higher production potentials than native plant communities, but the increase comes at a cost for inputs associated with maintenance of soil fertility. There is some misunderstanding regarding potential profitability of introduced forage and native rangeland livestock production systems. Some people believe that because some introduced forages can generally be grazed more heavily than native rangeland, the profit is proportionally more. Introduced forages, however, if not managed wisely, can increase input costs, but the producer may realize little, if any, increased production or profitability when compared to native rangeland systems.

Different management techniques are required for introduced forages relative to native rangeland. Native rangeland

The Oklahoma Cooperative Extension Service  
Bringing the University to You!

The Cooperative Extension Service is the largest, most successful informal educational organization in the world. It is a nationwide system funded and guided by a partnership of federal, state, and local governments that delivers information to help people help themselves through the land-grant university system.

Extension carries out programs in the broad categories of agriculture, natural resources and environment; family and consumer sciences; 4-H and other youth; and community resource development. Extension staff members live and work among the people they serve to help stimulate and educate Americans to plan ahead and cope with their problems.

Some characteristics of the Cooperative Extension system are:

- The federal, state, and local governments cooperatively share in its financial support and program direction.
- It is administered by the land-grant university as designated by the state legislature through an Extension director.
- Extension programs are nonpolitical, objective, and research-based information.
- It provides practical, problem-oriented education for people of all ages. It is designated to take the knowledge of the university to those persons who do not or cannot participate in the formal classroom instruction of the university.
- It utilizes research from university, government, and other sources to help people make their own decisions.
- More than a million volunteers help multiply the impact of the Extension professional staff.
- It dispenses no funds to the public.
- It is not a regulatory agency, but it does inform people of regulations and of their options in meeting them.
- Local programs are developed and carried out in full recognition of national problems and goals.
- The Extension staff educates people through personal contacts, meetings, demonstrations, and the mass media.
- Extension has the built-in flexibility to adjust its programs and subject matter to meet new needs. Activities shift from year to year as citizen groups and Extension workers close to the problems advise changes.

The Cooperative Extension Service is the largest, most successful informal educational organization in the world. It is a nationwide system funded and guided by a partnership of federal, state, and local governments that delivers information to help people help themselves through the land-grant university system.

Issued in furtherance of Cooperative Extension work, acts of May 8 and June 30, 1914, in cooperation with the U.S. Department of Agriculture, Robert E. Whitson, Director of Cooperative Extension Service, Oklahoma State University, Stillwater, Oklahoma. This publication is printed and issued by Oklahoma State University as authorized by the Vice President, Dean, and Director of the Division of Agricultural Sciences and Natural Resources and has been prepared and distributed at a cost of 42 cents per copy. 0703
